

API Integration breakdown

Sending the prompt

The application stores the prompt in variable called “generatedPrompt”. The request body uses `JSON.stringify()` to package the model name, message content (generatedPrompt) and the temperature setting into a JSON string. `Fetch()` sends the request body to the API using a POST request and then a response is sent back from the API.

Headers and Authorization tokens

The headers tell the server that the request body contains JSON data and provides the authorization token. The authorization token is a private access key that the AI service request to perform the request.

Processing the response

There is an if statement to check if the response from the API is okay. If the response is okay, it is converted into a JavaScript object so that the application can read and display it.

Handling errors

The try catch block is used for defensive programming during the request. The request is performed inside of the try block. Any error that occurs will be handled by the catch block displaying a message instead of leaving the failure unhandled.
